Pain continues to be undertreated, despite 2 decades that have witnessed the development of consensus-based guidelines for the management of cancer pain and intensive educational efforts on the part of professional societies, the philanthropic community, and industry. Undertreatment cannot be condoned, particularly in light of available evidence that pharmacotherapy with both opioid and nonopioid drugs can provide adequate relief to most patients. Although a multimodality strategy can augment pain relief, diminish the effect of pain that persists, and improve related outcomes, the mainstay approach to moderate or severe cancer pain continues to be opioid-based therapy. The “analgesic ladder,” which was promulgated by the World Health Organization in the late 1980s, was the first guideline to codify an opioid-based treatment for cancer pain. Combined with straightforward dosing guidelines, it has had a significant effect on practice around the world. Although more recent guidelines emphasize the need for flexibility and the potential value of skipping steps and selecting specific drugs based on patient assessment, all continue to emphasize the value of opioids for moderate to severe chronic pain, the importance of dose individualization through a process of repeated titration, the use of analgesic polypharmacy in many cases, and the ongoing need to manage side effects to optimize the balance between pain relief and adverse drug effects.

Update on Breakthrough Pain

Breakthrough pain (BTP)—episodic pain that “breaks through” analgesic therapy in populations with chronic pain—is a serious clinical problem, likely afflicting thousands of patients. Despite its seriousness, BTP is underappreciated by clinicians.

The terminology used to describe BTP has been
widely debated, and various definitions have been created and published in the medical literature. The broadest definition is probably the most useful: BTP is any transient and clinically significant pain that flares over baseline pain that is adequately controlled by any analgesic regimen.

**Epidemiology, Impact, and Characteristics**

Studies of populations of patients with cancer pain have revealed that 50% to 90% of them experience BTP. A survey of hospice patients without cancer, 63% had BTP. A survey of chronically noncancer pain patients identified a prevalence of 74% among those taking opioid analgesics. Among cancer patients, BTP is associated with a more severe pain syndrome, reduced responsiveness to opioid therapy, pain-related functional impairment and psychological distress, and an increase in the economic burden for patients and the healthcare system.

Although characteristics and location of a patient's BTP are usually the same as those for the patient's baseline pain, there are notable differences in how BTP manifests between individuals. The frequency of flares varies from fewer than 1 per day to many per hour; most patients experience approximately 3 flares per day. Most episodes are brief (<30 minutes), but on occasion a patient will experience BTP for hours. BTP can reach peak intensity over a period of minutes, but can also increase more gradually. BTP can appear without warning or be predictable, and predictable pain has a broad array of potential precipitants. One type of BTP, called end of dose failure, occurs at the end of a dosing interval. The etiologies and types of mechanisms underlying BTP are as variable as those of the baseline pain to which they usually relate.

The optimal management of BTP depends on a detailed assessment. If the information available does not allow a detailed understanding, further work-up with imaging studies or other tests should be considered.

**Management of Breakthrough Pain**

There have been few studies of BTP. A rational empiric approach includes 3 steps: 1) treatment of the etiology or precipitating causes, 2) optimization of the baseline analgesic regimen, and 3) trial of symptomatic interventions.

**Treatment of the Etiology or Precipitating Causes**

Primary therapy for the cause of the BTP, such as radiotherapy to a bony lesion, should be provided if it is feasible, does not subject the patient to excessive risk, has a reasonable likelihood of reducing the frequency or intensity of the pain, and is consistent with the goals of care. Cases of BTP that are precipitated by specific phenomena may be amenable to primary management of the precipitant. Examples include the treatment of cough-related pain with an antitussive and the treatment of suprapubic pain caused by bladder spasm with an anticholinergic drug.

**Optimizing the Baseline Analgesic Regimen**

Patients with end-of-dose failure may be helped by shortening the dosing interval or increasing the standing dose. Even those with BTP at other times may benefit, however, if the standing analgesic dose is increased. An empiric increase in the regularly scheduled opioid dose to a level just below treatment-limiting side effects should be considered as a trial in all patients with BTP, even those with well-controlled baseline pain.

**Trials of Symptomatic Interventions**

The use of a rescue dose—a supplemental dose of an analgesic provided on an as-needed basis in combination with the regularly scheduled analgesic—is the most widely accepted approach for cancer-related BTP. The rescue drug could be a nonopioid or an adjuvant analgesic such as ketamine, but most experience has revolved around the use of opioids. Although opioid rescue dosing is being used for BTP associated with chronic noncancer pain, there are no published safety and effectiveness data to date and the treatment should be used only if the assessment clearly suggests that benefits exceed risks.

There has been little systematic study of the opioid rescue dose. Some guidelines suggest that the rescue drug should be identical to the regularly scheduled opioid, but there is no evidence to support this recommendation. Although the typical BTP time course suggests that the ideal rescue drug should have a rapid onset of analgesia and a short duration of action, rescue dosing with a short-acting oral opioid drug has been widely used. There is presumably substantial variation in patient responses, and studies are needed to better assess the impact of onset time for different populations with BTP.

Notwithstanding the latter observation, a rapid onset of analgesia does appear to be favored by those with BTP. Oral transmucosal fentanyl citrate (OTFC) was developed on this basis. The development of OTFC led to refined protocols for future clinical trials on BTP. A second rapid-onset formulation, the fentanyl buccal tablet (FBT), is now available. Other formulations are in development for BTP, most attempting to replicate the concept of rapid onset via a transmucosally delivered lipophilic opioid.

Based on clinical experience, the appropriate dose of the rescue drug has been proposed to be approximately 5% to 15% of the total daily opioid dose. Controlled trials did not confirm this guideline for OTFC or FBT and dose titration from a low dose (200 mcg or 400 mcg of OTFC; 100 mcg or 200 mcg of FBT) is recommended in all cases. One study of morphine-treated patients indicated that 20% of the daily dose could be used safely. Regardless of the starting dose, titration of the rescue drug based on the patient’s response is an important principle.

The timing of the rescue dose is conventionally determined by the route of administration. Most guidelines suggest a minimum interval of 2 hours for oral administration and 15 to 60 minutes for parenteral and oral
transmucosal administration.

If the rescue dose causes treatment-limiting side effects, various strategies may be considered in a manner identical to the approach to patients with a poor response to a regularly scheduled opioid regimen. These include rotation of the rescue drug or the entire regimen to a different opioid, coadministration of a drug to treat the side effect, and coadministration of a pharmacologic or nonpharmacologic approach to reduce the opioid requirement.

The importance of the opioid rescue dose should not obscure the potential benefits of other approaches. For example, neuropathic BTP may respond to the administration of an adjuvant analgesic, usually an antidepressant or anticonvulsant. Nonpharmacologic treatments are very helpful for some and include cognitive strategies (particularly if BTP is predictable), physical therapy, bracing, and various complementary treatments. Intervventional approaches, such as injection therapies, neural blockade, and neuromodulation, must be considered if BTP is refractory to other strategies.

References

**Routes of Administration**

Although the oral and transdermal routes are preferred, alternative routes of administration will be required for a substantial number of patients at some point in their course.

- **Buccal:** Supporting data meager (for oral suspensions, etc.). Method currently unavailable and impractical.
- **Epidural:** Repetitive bolus; continuous infusion.
- **Intracerebroventricular:** Rarely indicated. Limited survey data available.
- **Intranasal:** Available for buprenorphine; not used in cancer pain management.
- **Intrathecal:** Repetitive bolus; continuous infusion. Clearest indication is pain in lower body with poor relief and side effects from systemic opioids. Epidural catheter can be percutaneous (from lumbar region or tunneled to abdomen) or connected to subcutaneous portal, depending on patient’s life expectancy. Intrathecal usually administered via implanted pump. Benefits of long-term intrathecal infusion in selected patients demonstrated in randomized trial (Smith TJ, et al. J Clin Oncol. 2002;20:4040-4049). Morphine, hydromorphone, fentanyl, and others in use, combined with local anesthetic or clonidine.
- **Intravenous:** Repetitive bolus; continuous infusion; PCA (with or without infusion). Indicated if other routes are unavailable or riot tolerated, or if patient has an indwelling I.V. access device.
- **Oral:** Preferred route of administration for long-acting opioids in cancer pain management. Transdermal available for fentanyl.
- **Oral transmucosal:** Controlled clinical studies of oral transmucosal fentanyl citrate show efficacy in cancer-related breakthrough pain.
- **Rectal:** Available for morphine, oxymorphone, and hydromorphone. Although few studies available, commonly used as if dose is equianalgesic to oral dose.
- **Subcutaneous:** Repetitive bolus; continuous infusion; continuous infusion with PCA. Ambulatory infusion pumps permit outpatient continuous infusion. Can be accomplished with any parenteral drug. Drug mixtures to treat multiple symptoms and long-term hydration also feasible by this route.
- **Sublingual:** Buprenorphine effective, and sublingual tablet available in the United States. Efficacy of morphine controversial.
- **Transdermal:** Available for fentanyl.
**NONOPIOD ANALGESICS**

Patients who present with mild to moderate pain should be treated with a nonopioid analgesic. An adjuvant drug should be used if a specific indication for one exists. Adjuvant drugs include treatments for opioid side effects or other comorbid conditions and “adjuvant analgesics,” which are drugs with primary indications other than pain that are analgesic in selected circumstances.

Patients who fail the 1st-step regimen or who present with moderate pain should be treated with an oral opioid for moderate pain as well as with a nonopioid analgesic and an adjuvant drug, if the clinician has evidence for the efficacy of the adjuvant. In current clinical practice, the 2nd step is applied flexibly; it may be skipped in lieu of treatment with a 3rd-step drug or primary treatment with an adjuvant analgesic in selected syndromes. In the treatment of continuous pain, analgesics should be given on a regular basis—“by the clock”—so that the next dose is given before the effect of the previous one wears off. These short-acting drugs are also used as “rescue” medications, given as needed for breakthrough pain during treatment with a long-acting opioid.

Patients who fail the 2nd-step regimen or who present with moderate to severe pain should be treated with an opioid indicated for such pain. The clinician should consider the addition of a nonopioid analgesic or an adjuvant drug. In the treatment of persistent pain, analgesics should be given on a regular basis—"by the clock"—so that the next dose is given before the effect of the previous one wears off.

Comments

See Key, Endnotes, and Routes of Administration

Standard of comparison for opioids. Multiple routes available (see Routes of Administration). Survey data indicate that a switch from immediate-release morphine to controlled-release morphine should be done at same milligram dose. Available in several modified-release formulations for once-daily or twice-daily administration.

Multiple routes available (see Routes of Administration). May become available as a modified-release formulation with a long duration of effect.

Not preferred for cancer pain because of potential toxicity.

Available as a single agent and in combination with aspirin or acetaminophen; at higher doses used as a single agent for patients with severe pain or who have developed tolerance; available in a modified-release formulation for twice-daily or three times daily administration; no parenteral formulation.

Available in a modified-release formulation for twice-daily dosing.

Efficacy and safety in the treatment of cancer-related breakthrough pain has been established in controlled trials. Onset is faster than oral rescue doses. No relationship exists between effective OTFC rescue dose and baseline opioid dose. Therefore, all patients should be started on a relatively low dose (200 mcg or 400 mcg) and dose should be titrated to effect. This contrasts with guidelines recommending rescue opioid dosing at 5% to 15% of total daily opioid dose.

Fraction absorbed transmucosally is twice that of OTFC, and therefore is twice as potent; peak effect is earlier than that of OTFC.

May cause withdrawal symptoms in opioid-dependent patients; has ceiling for analgesia and less abuse potential; sublingual tablets available in United States; may be useful in nondependent/nontolerant patients with cancer pain (ie, on the 2nd step of the analgesic ladder).

Agonist–antagonist. No oral formulation; may cause withdrawal symptoms in patients who are physically dependent to an opioid; not recommended for cancer pain therapy.

Agonist–antagonist. No oral formulation; may cause withdrawal symptoms in patients who are physically dependent to an opioid; not recommended for cancer pain therapy.

Agonist–antagonist. Oral preparation combined with naloxone or acetaminophen in United States; may cause withdrawal symptoms in patients who are physically dependent to an opioid; not recommended for cancer pain therapy.

Patches of different sizes can deliver 12, 25, 50, 75, or 100 mcg/h. Dosing interval is 48 to 72 h. Dose usually adjusted every 3 d if needed, and multiple patches may be used.

With long half-life, accumulation occurs after dose is begun or increased.

Available as a racemate; the o-isomer is an NMDA antagonist, which may account for unexpectedly high potency in some patients who are switched from another drug. This uncertainty about potency, together with concern about a long and variable half-life, necessitates caution in the use of this drug. When a patient is switched from another drug, the calculated equianalgesic dose should be reduced by 75% to 90%. Prolonged monitoring may be needed during dose titration. Multiple routes available.

Available formulations vary in duration of effect—from 8-12 h, to 12-24 h, to 24 h.

Available as an immediate-release agent and in combination with aspirin or acetaminophen; no parenteral formulation.

Available as an immediate-release agent.
**ADJUVANT ANALGESICS**

Adjuvant analgesics comprise diverse classes of drugs that have other indications but also have analgesic properties in specific circumstances. These drugs should be used when the clinician has evidence of their utility.

**ENDNOTES**

* Consider using lower than recommended starting dose in the elderly, in patients on multiple drugs, and in those with renal insufficiency (one half to two thirds recommended dose). Doses must be individualized. Low initial doses should be titrated upward if tolerated and clinical effect is inadequate. Doses can be increased in weekly increments. Studies of NSAIDs in the cancer population are meager; thus dosing guidelines are empiric.

† Although clinical experience suggests that any of the NSAIDs may be analgesic, pain is an approved indication only for those drugs noted.

‡ Half-life of aspirin increases with dose.

.§ At relatively high doses, consider monitoring for adverse effects, eg, by checking for occult fecal blood or for changes in liver function tests, blood urea nitrogen and creatinine assessments, or urinalysis.

‖ Oral dose that provides analgesia equivalent to 650 mg of aspirin. Starting dose may be higher or lower, and dose titration is needed after therapy is begun.

¶ Dose that provides analgesia equivalent to 10 mg of IM morphine. The equianalgesic dose should not be interpreted as the starting, standard, or maximum dose, but rather as a guide for changing routes of administration. Depending on patient characteristics and prior opioid exposure, the starting dose can be lower or higher, and dose titration—either upward or downward—is repeatedly necessary in virtually all patients.

** Extensive survey data suggest that the relative potency of IM to PO morphine of 1:6 changes to 1:2 or 1:3 with long-term dosing.
Patient Guide to

MANAGEMENT OF CANCER PAIN

In order to help your clinician adequately monitor and treat your pain, it is important for you or a member of your family to keep a daily diary of your pain. There are several ways to measure your pain. One way is by selecting a number on a scale from 0 to 10. This scale is called a pain rating: “0” means no pain, and “10” means you have the worst pain imaginable.

Use a diary like the one shown below to record the date, time of day, a pain scale rating, and things you did to make the pain better.

### Pain Rating Scale
